1 Introduction

This report is a follow-up of an internship realized during the summer of 2025. This internship is part of a University program for third year students to have an introduction to research at Umons.
To this end, a student follows a PhD student and assists them in their work.

In my case, the PhD student supervising this internship is Aqeel Ahmed. His PhD is about Radio Frequency Fingerprinting (RFFI) of LoRa IQ signals using Deep Learning (DL) algorithms.
In a recent survey [1], he describes fingerprints as :

> *The entangled features of electronic hardware originating from the manufacturing process.*

He then describes RFFI as :

> *The process of extracting those features from the radio signal of the device with hardware imperfections that make the transmitter distinguishable among others even if they are from the same model and manufacturer [2].*

Aqeel, in the same survey [1], notes the lack of available data for LoRa RFFI. Due to this lack of databases, which is needed for DL model training, the creation of them is an important subject leading us to the objective of this internship.

1.1 Objective

The objective of this internship is to assist Aqeel in the collection of new LoRa IQ samples to experiment with Radio Fingerprinting classification with deep learning models. To this end, the collected samples are coming from multiples LoRa capable devices and labelled per device and time. Those captures are to be well classified and shouldn't take too long to make.

1.2 Overview

Section 2 explains the basic knowledge required to understand LoRa related discussions in this report.
Section 3 presents the material used, the structure of experiments as well as the different scenarios tested. A discussion on the possible implementations and transmission strategy is also made to assess the most reliable method.
A description of the selected implementation is made in section 4.
The results and their quality are assessed and discussed in section 5.
Finally, in section 6, propositions of improvements are presented and the conclusion of this work is done.

2 LoRa Basics

In this section, the essentials of the LoRA modulation technique (section 2.1), preamble format (section 2.2) and demodulation technique (section 2.3) are discussed to understand their uses in the experiments.

2.1 Chirp Spread Spectrum modulation

LoRa is a long-range, low-power, proprietary radio interface. It is based on a Chirp Spread Spectrum (CSS) modulation technique. The basic element of this technique is called a chirp. A chirp is a sinusoidal signal whose frequency varies linearly over time. Details on the underlying math can be found in a recent article [3] explaining CSS modulation and the key advances made to understand it. To understand the experiments made in this paper, only the frequency domain is explored and explained.

There are three necessary parameters for LoRa communication : a carrier frequency (F_c), a bandwidth (B) and spreading factor (SF).
The carrier frequency of the signal is set in Europe as 868 MHz. Finally, the spreading factor represents the number of bits carried in a LoRa symbol. For example, with an SF of 7, a LoRa symbol can represent a value ranging from 0 to $2^7 - 1 = 127$.

LoRa symbols are chrips whose duration T depends on the bandwidth B and spreading factor SF as the equation 1 shows.

$$T = \frac{2^{SF}}{B} \tag{1}$$

A LoRa symbol frequency varies from $F_c - B/2$ to $F_c + B/2$ linearly as shown in the Figure 1a. It implies that when a signal reaches a frequency of $F_c + B/2$ (resp. $F_c - B/2$), wraps up to $F_c - B/2$ (resp. $F_c + B/2$) before varying linearly again.

The value represented depends on the start (and final) frequency of the LoRa symbol. For a symbol of value s, the starting frequency $f_0 = F_c - B/2 + \frac{sB}{2^{SF}}$. Intuitively, the value is represented by the "frequency phase" of the received signal. It is possible to observe that the symbol represented in Figure 1b is a baseup chirp because its starting frequency is $F_c - B/2$.
A baseup chirp represents a value of 0 and varies from $F_c - B/2$ to $F_c + B/2$. Similarly, a base-down chirp starts at $F_c + B/2$ and ends at $F_c - B/2$, decreasing linearly rather than increasing.

(a) LoRa Symbol

(b) baseup chirp

Figure 1: Chirps of duration T and bandwidth B in the frequency domain (frequency with respect to time). The frequency axis is relative to the carrier frequency F_c.

2.2 Preamble

A LoRa frame is composed of 3 parts: the preamble part, the Start of Frame Delimiter (SFD) and the actual data symbols. The preamble part is composed of 8 or more baseup chirps and a sync word part composed of two symbols. The SFD is composed of 2.25 base-down chirps.

A captured representation of a preamble + SFD can be seen in Figure 2.

Figure 2: Spectrogram of a captured LoRa preamble and SFD from inspectrum[1]

The data symbols part isn't discussed because only the preamble and SFD parts are used for the deep learning algorithms. By taking more of the

[1]inspectrum is an open source radio signal analyser. Its source code can be found at `https://github.com/miek/inspectrum`

frame, for example the header, the DL model is capable of detecting features not specific to hardware impairments. The preamble and SFD part forms a small stable set of symbols only impacted by hardware impairments.

2.3 Demodulation

The demodulation technique used in the experiments comes from a comprehensive paper named *From Demodulation to Decoding* [4]. The method proposed can be described in 4 steps graphically explained in Figure 3.

i. Retrieve the sampled data containing a LoRa symbol with a sampling frequency f_{samp} of at least two times the bandwidth Bw.

ii. Multiply the retrieved signal, of initial frequency f_0, with a base downchirp to obtain two constant signals with frequency f_0 and $f_0 - Bw$.

iii. Apply a Fast Fourier Transform (FFT) on the result of the multiplication. This gives two distinct peaks at f_0 and $f_{samp} - Bw + f_0$ as shown in Figure 3(iii).

iv. The paper then proposes two options to merge those peaks. A Fine-Grained Phase Alignment (FPA) and a Coarse-grained Phase Alignment. CPA is much less computationally heavy than FPA and has marginally worst results. In either case, the result gives an FFT peak at f_0.

Figure 3: Graphical explanation used in the reference paper [4].

3 Methodology

In this section, the methodology of the experiments is presented. To this end, the material (section 3.1), the individual setups and the overall layout (section 3.2), the transmission method (section 3.3) and the scenarios of the experiments (section 3.4) are discussed.

3.1 Material

The use of material in our experiments can be separated into two parts :

The receiver Part uses a laptop, an USRP Software Defined Radio (SDR) with its enclosure kit and an antenna.

unsure of the exact model (B210 or B200?)

The transmitter Part uses a laptop, 4 StarTech USB hubs (ST7200USBM), 20 Arduino MKR1310 devices with antenna, a Velleman 5V lab power supply (LABPS3005SM), soldered copper wires to supply the Arduino devices and a handmade frame to attach the Arduino devices to.

3.2 Setups and Layout of the experiments

First, the singular setups of the receiver and transmitter part are discussed then the overall layout is presented.

The receiver setup is straight forward : the laptop is connected to the USRP SDR by USB. The SDR antenna is vertical. Figure 4 shows a schematic of the receiver setup.

Figure 4: Receiver side schematic. The receiver laptop is connected to the USRP by USB. The SDR captures signals through its antenna.

photo of the Receiver part in appendix

The transmitter setup is more complex : the laptop is connected to a first USB HUB on which the 3 other USB hubs are connected to form a star topology. The choice of such a topology is to flatten the USB communication delay with all 20 Arduino devices. The Arduino devices are connected to the outermost USB hubs and powered externally by the lab power supply through their back pins with the soldered cables. The antennas connected to the devices are also vertical to have the same polarization as the SDR's antenna.
The power supply is programmed with 5 V of tension and 1 A of current.
The Figure 5 shows the USB connections from the laptop to the Arduino devices. Figure 6 shows the power supply schematic of the transmitter side.

add a reference for the polarization effect

Figure 5: Receiver side USB connections schematic. The transmitter laptop is connected to the top level USB hub on which the outermost hubs are connected. Twenty devices with antennas are then connected to the outermost hubs.

The layout of an experiment has tree components : The receiver and transmitter part composed of the receiver and transmitter setup respectively and a smartphone used as a modem for the communications between them. All of those components are in line of sight of each other to have the best possible transmission, reception and communication. Figure 7 shows a representation of the layout.

Add photos of the layout in appendix

Figure 6: Receiver side power supply schematic. The composition is as follows : five sets of devices are connected in parallel to the lab power supply. In a set all devices are connected in series through their back pins (VIN and GND).

Figure 7: Representation of an experiment layout. All components have line of sight with the others. The smartphone is used as a connection bridge between the receiver and transmitter side.

3.3 Transmission method

The method to transmit and receive frames is discussed with two proposed methods :

Round-robin method (RR) : each device sends a single frame then sleeps until all other devices sent their frame. This creates a cycle where each device sends one frame and waits for the next cycle. The method cycles as explained until all frames from each device is sent. This cycling scheme

implies to change from one device sending to another 20 times per cycle.

One by One method (ObO) : each device sends all the frames it has to in a single burst. A cycle is defined as all the transmissions from a single device. The method cycles for each device until all frames from each device is sent. This cycling scheme implies to change from one device sending to another only 20 times in total.

Comparison : the methods are compared by (1) speed, (2) ease of implementation, (3) misclassification and (4) quality.

(1) Each method is similar in terms of speed, though ObO can be faster because there are fewer synchronization constraints.

(2) Both implementations have their specificities, but none are substantially harder to implement then the other.

(3) Misclassification are most likely to occur when changing devices. The number of changes in RR makes it prone to misclassifications. In contrast, ObO has way fewer device changes making it less prone to misclassification.

(4) The environment can vary over time (temperature, humidity, ...) and the Deep Learning model is capable of identifying those variations and classify devices with respect to them. In RR, those variations are present on all devices because a cycle is short. On the other hand, in ObO, those variations can appear in the captures because the time between the transmissions of the first and last device is much longer.

Selection : although the quality of the captures from ObO can be lower than in RR, because of time constraints and difficulty to make the Round-robin method work flawlessly, the One by One method is used in the experiments.

3.4 Scenarios

Captures are made in two environments at different distances. Some parameters are shared between each scenario. They are : the spreading factor (SF), bandwidth (Bw), carrier frequency (F_c), time between 2 frame transmissions (*period*), number of frames a device has to send, number of devices, gain on the receiver SDR and sampling rate (F_s).
The values of the shared parameters are shown in Table 1.

Table 1: Shared parameters values

SF	Bw (kHz)	F_c (MHz)	*period* (ms)
7	125	868	200
$frames\ per\ device$	$number\ of\ devices$	$Gain$ (dB)	F_s (samples/s)
550	20	+40	10^6

Inside : The sports hall in the Vésale building on the Nimy Campus at Umons is used as the inside environment. The distance varies from 5 m to 40 m with an initial step of 5 m then steps of 10 m until 40 m. Thus, the resulting captures are at 5 m, 10 m, 20 m, 30 m and 40 m.

Outside : The grass field between the DeVinci building and the "bâtiment 4" on the Nimy Campus at Umons is used as the outside environment. The distance varies from 5 m to 50 m with an initial step of 5 m then steps of 10 m until 50 m. Thus, the resulting captures are at 5 m, 10 m, 20 m, 30 m, 40 m and 50 m.

I'm unsure on how to locate the environments

4 Implementation

5 Results

6 Conclusion

6.1 Possible improvements

Presenting the issues still in place and give an idea on how we might be able to fix them
